ABSTRACT

This study aims to investigate microstructure, hardness, corrosion and wear properties of FeCrNiMo-based coating produced on AISI 1040 steel by using laser welding method. Microstructure properties and phase formation were examined by SEM-EDS and XRD. The hardness measurement was made by using a microhardness device along a line from the upper surface of the coating to the substrate. The wear tests of both the substrate and coating layer were made with a scratch test device. SEM examinations showed that the coating layer had a dendritic microstructure and was uniformly bonded to the substrate. The coating layer was harder than the substrate. According to wear tests, the friction coefficient of the coating layer was lower compared to the substrate. Substrate and coating layer were immersed in an aqueous solution of %3.5 NaCl for potentiodynamic measurements. Corrosion results showed that coating of the AISI 1040 steel with FeCrNiMo increased the corrosion resistance.

Laser coating, microstructure, wear, corrosion

INTRODUCTION

The wear and corrosion of machine parts is the leading problem encountered in the industry. Surface coating process is widely used to increase corrosion and wear resistance. Many coating methods are used to improve the properties of the surfaces. Basically, coating methods are classified as welding-based coating methods [1,2], thermal spraying [3] and chemical and physical vapor deposition methods [4,5]. Welding-based surface coating methods generally include plasma-transferred arc, gas tungsten arc, laser beam, submerged, electro-slag and electron beam welding processes [6–8]. Laser coating is a unique process that produces a coating metallurgically bonded to the substrate, which finds an increasing application in surface engineering field. A laser beam having a high energy density is a heat source used to melt the coating material and a limited portion of the substrate. The coating materials are in the form of powder, bar or layer. Compared to other coating techniques, laser coating has many advanced properties. These include a metallurgical bonding between the coating and the substrate, a very fine grained microstructure, a low melt rate and a limited heat-affected zone (HAZ) [9–11]. Due to its high corrosion resistance and high wear resistance, the FeCrNiMo alloy is often used under atmospheric conditions in acidic and tribological environments [12]. In this study, a FeNiCrMo based alloy wire was produced as a coating layer on AISI 1040 steel surface by laser welding. Microstructure, phase formation, corrosion and wear properties of the produced coating were investigated.

EXPERIMENTAL STUDIES

AISI 1040 steel in the dimensions of 20 x 10 x 80 mm was used as the substrate material in the surface coating processes. Prior to the laser coating method, the surface of the steel material was cleaned with acetone. Alloy wires with a 0.6 mm diameter were coated on AISI 1040 steel surface by using an Or-Laser brand laser welding machine with the power of 200 Watts. Table 1 shows the chemical composition of the wire and the substrate used in the coating. Fig. 1 shows the the surface coating process with laser welding. The laser coating process was performed in the form of coating passes.

The samples were taken in the dimensions of 10 mm x 10 mm x 10 mm from the middle zone of the coating material for the microstructure examinations and wear test. Coating materials passed through the
Potentiodynamic sweeping was performed in range of ± 0.25 V and 1 mV/s sweeping rate. The polarization resistance values were calculated by using Stern and Geary equation.

**RESULTS AND DISCUSSION**

Fig. 4 shows SEM images of the FeCrNiMo-based coating produced on the AISI 1040 steel surface by the laser welding. The coating thickness was observed to be about 250 µm (Fig. 4a). It is also clearly seen in the same SEM image that the coating layer was composed of overlapped multi-passes. Coating layer formed of cellular structure and dendritic structure. Dendrites occurred in the opposite direction of the heat flow (Fig. 4b). This coating microstructure contained austenite and α-ferrite. Approximate ratio of these structures was determined by means of the Schaeffler diagram in Fig. 4c. These structures formed as solid solutions. No pore or crack formation was found in the coating layer. MAP-EDS analysis was carried out to see how the element distribution in the coating layer is, which is shown in Fig. 5. There was a homogeneous distribution in the coating layer. No oxide formation occurred.

Corrosion measurements were obtained by using a system consisting of a Reference 3000 Potentiostat / Galvanostat / ZRA corrosion system (Fig. 3). Corrosion experiments were carried out after the samples were left waiting for 1 h at room temperature in a 3.5 wt.% NaCl solution (pH 3). A conventional three-electrode cell was used for all the electrochemical measurements. A saturated calomel electrode (SCE) was used as a reference electrode, platinum foil as a counter electrode and coatings as the working electrode.

| Table 1. Chemical composition of substrate and coating wire (wt.%) |

**Table 1. Chemical composition of substrate and coating wire (wt.%)**
cal composition of the selected coating wire. This indicated that the coating process reached its goal. In order to show the elemental difference between the coating layer and substrate, line EDS was performed between the coating and substrate. Fig. 7 shows line EDS. Cr, Ni, and Mn elements increased significantly in the coating layer.

Fig. 8 shows the XRD analysis of the coating produced on the AISI 1040 steel surface by the laser welding. The coating layer consisted of α-Fe (ferrite), γ-Fe (austenite) and M23C6 phases. The letter M represents the elements Fe, Cr, and Mo. While austenite peak occurred at the angle of 43.6, 50.6 and 74.7 2θ angles, the ferrite peak occurred at the angles of 64.9 and 81.9 2θ. The intensity of the M23C6 carbide peak was very low compared to the other two phases. The phases occurring in this study are also similar to those in the literature [14]. Since the coating layer had Cr-Ni content, no oxide phase was found. This shows that it is corrosion resistant.

Wear test of the coating layer and the substrate was conducted in the form of micro-scratches. A Rockwell indenter was used as the abrasive indenter. The scratch size was chosen as 2 mm in both samples. Fig. 10 shows wear graphs showing the friction coefficients of the coating layer and substrate. The applied load was measured as 9.55 N, which was maximum. The wear test was completed in 14 seconds. Friction coefficient graphs were also drawn as friction coefficient versus time. When the graph was examined, it was understood that the friction coefficient of the coating layer (~0.17) was lower than the friction coefficient of the substrate (~0.23). This decrease was associated with the solid solution strengthening and the dispersion strengthening of the carbides. Fluctuations were observed in the friction coefficient values of the coating layer. This was related to the fact that the phases were not homogeneously distributed in some regions of the coating. Fig. 11 shows optical images of the wear marks. It was seen that plastic deformation was more intense in the substrate. Flaking was observed in both wear marks. Gong et al [15] presented a study on influence
of heat treatment on microstructure and mechanical properties of FeCrNi coating produced by laser cladding. The results of the study showed that as the heat treatment temperature increased, the wear resistance decreased although the maximum tensile strength was obtained.

The potentiodynamic polarization curves of the substrate and coating layer are illustrated in Fig. 12. The corrosion measurement data are summarized in Table 2. Corrosion potential ($E_{\text{corr}}$), anodic and cathodic Tafel slopes ($\beta_a$ and $\beta_c$), corrosion resistance ($R_p$), corrosion rate and corrosion current ($I_{\text{corr}}$) were found from Tafel curves. $R_p$ was calculated by the Stern and Geary equation [16].

$$I_{\text{corr}} = \frac{\beta_a \beta_c}{2.303 \times R_p (\beta_a + \beta_c)}$$

where $I_{\text{corr}}$ is the corrosion current density in $\mu A \ cm^{-2}$, $R_p$ is the corrosion resistance in $k\Omega \ cm^2$, and $\beta_a$ and $\beta_c$ are the anodic and cathodic Tafel slopes in $V$ or $mV$, respectively. The corrosion potential ($E_{\text{corr}}$) values of the substrate and coating layer are slightly different. While $E_{\text{corr}}$ of substrate is $-435$ mV, $E_{\text{corr}}$ of coating layer is $-293$ mV. The ($R_p$ of the substrate and coating layer are 20.70 $k\Omega \ cm^2$ and 25.57 $k\Omega \ cm^2$, respectively. $R_p$ of the coating layer was increased by about 23.4 % compared to that of the substrate. The key element that determines the corrosion resistance of the coating layer is chromium. Cr forms a very thin film on the surface of the material against corrosion attacks. The protective film called passive layer or passive film [17]. The Ni element has a regulatory effect on the ductility and toughness properties of the material. The Mo element provides the continuity of the passive layer formed to protect from corrosion [18, 19]. Qiao et al [20] studied the corrosion behavior of HVOF-sprayed Fe-based alloy coating in various solutions. It has been observed that the coating layer exhibits different corrosion resistances in different solutions. However, it has been reported that the coating layer has higher corrosion resistance than the bottom layer. Our study showed similar results with these results.

**CONCLUSION**

1. In this study, FeCrNiMo based alloy wire was successfully coated on AISI 1040 steel surface with the laser welding technique.
2. It is seen from the SEM images that the coating had dendritic and cell morphology. This shows similarity with the literature. According to the XRD analyses, $\alpha$-Fe (ferrite), $\gamma$-Fe (austenite) and M23C6 phases formed as phases in the structure. It was also found by the Schaeffler diagram that these phases can form. Majority of the structure had an austenite character.
3. The hardness of the coating layer was about two times more than that of the substrate. This increase in the hardness was caused by solid solution and M23C6 carbides formed in the structure.
4. Wear tests of the coating layer and the substrate were made in the form of micro-scratches. A decrease was experienced in the friction coefficient of the coating layer compared to the substrate. This was caused by strength increasing mechanisms.
5. The corrosion potentials of the substrate and coating layer are slightly different. Coating of FeCrNiMo on AISI 1040 steel has increased corrosion resistance by 23.4 %. Cr contributes directly to the corrosion resistance, whereas Mo contributes indirectly.
